

XV. MINOR CHEMICAL COMPOSITION OF BOTTOM SEDIMENTS FROM THE CENTRAL PACIFIC WAKE-TAHITI TRANSECT

Naoki Mita, Seizo Nakao, and Komi Kato

Introduction

The moisture content and the minor element contents were determined for 115 sediment samples collected from the GH80-1 survey traverses of the Central Pacific Wake-Tahiti Transect. The minor elements determined were Mn, Fe, Co, Ni, Cu, Zn, and Pb. The data for evaluating the distribution of these components in the ocean floor of the Central Pacific Basin and its northern and southern vicinities were obtained. These sediment samples comprises 24 surface sediment samples and 91 segments from core samples ranging in depth to several meters below the sea bottom.

Principal characteristics of the concentration and horizontal distribution of each component in the gross sediment samples are described in this chapter, as well as the relations among the elements. More detailed discussions of the behavior of the minor elements in regard to the sedimentary facies, depth below the sea bottom, etc. will be presented elsewhere.

Method

Preparation of samples

Raw sediment samples were stored in polystyrene bottles. Supernatant water of the sediment samples was removed from each bottle. Samples were mixed well, then transferred to paper bags respectively, and were dried in the sun for a few days. After drying enough, samples were rough-crushed over the bags with a wooden hammer. Crushed samples were transferred and spread on clean papers. The crushed samples of about 10 g selected by the quartering method were stored in small paper bags. Coarse grains such as tiny manganese nodules (coarser than 2 mm) were removed and transferred to polyethylene bags from the selected samples.

The selected samples were ground under the size of 150 mesh. The ground samples were stored in paper bags and then allowed to stand for a week in the atmosphere. After standing, the samples were stored in polyethylene bags and these samples were used for analysis.

For the analysis, we weighed out the samples for the determination of moisture and of minor elements almost at the same time, in order that the minor element contents must be converted to a dry basis by separate moisture determination on the samples.

Determination of moisture content (-H₂O)

About 0.5 g of the sample in the weighing bottle whose weight was known was weighed exactly. The bottle containing the sample was dried for 3 hours at 110°C to constant weight. The weight of the weighing bottle with the sample was weighed after cooling

in a desiccator. The weight of the dried sample was calculated through subtracting the weight of the bottle from that mentioned above. The moisture content was calculated from the loss in weight.

Determination of minor element contents

About 0.25 g of the sample was weighed out exactly into a platinum dish (75 ml). A small amount of water was added and moistened. Two ml of nitric acid, 5 ml of perchloric acid and 10 ml of hydrofluoric acid were added and then mixed well. The dish was heated to dryness on a sand bath. After dried, the dish was cooled. The inside of the dish was washed with a small amount of water. Then, 3 ml of perchloric acid was added and the dish was heated to dryness. After cooled, 2.5 ml of hydrochloric acid (6N) were added. The dish was heated on a hot plate weakly until the salts were dissolved. After cooling, a small amount of water was added and the dish was heated to dissolve the salts and then cooled. The solution was transferred into a volumetric flask (50 ml) washing with water. The solution was diluted to the mark with water. The minor elements (Mn, Fe, Co, Ni, Cu, Zn, and Pb) were determined by the atomic absorption spectroscopy, following the method by TERASHIMA (1971) after some modifications which concern the elimination of diverse interferences.

Results and discussions

The contents of the minor elements (Mn, Fe, Co, Ni, Cu, Zn, and Pb) and the moisture ($-H_2O$) for the 115 sediment samples are shown in Appendix XV-1, which also shows the metal contents of manganese nodules determined by USUI and MOCHIZUKI (Chap. XVI, this cruise report) for convenience. The data in the appendix are analytical values of air-dried samples. Since the moisture content of the air-dried sample is changeable depending of the humidity of air, the minor element contents must be converted to a dry basis ($110^{\circ}C$) by separate moisture determination on the sample. The following results and discussion are described on a dry basis.

The contents of each components and the characteristics of their horizontal distributions

The average, the minimum, and the maximum contents of each component are shown in Table XV-1. The histograms of each component are shown in Fig. XV-1. The dotted curves drawn with the histograms are normal distribution curves by the average and standard deviation.

As can be seen from the histograms, the contents of each component are widely distributed in the bottom sediments. Three types of the distribution of each component are obtained by comparing their histograms with normal distribution curves. One is

Table XV-1 Average, minimum, and maximum chemical composition of the bottom sediments. The value was recalculated for 115 samples on the basis of dried state ($110^{\circ}C$).

	H ₂ O-(%)	Mn(%)	Fe(%)	Cu(ppm)	Ni(ppm)	Co(ppm)	Zn(ppm)	Pb(ppm)
Average	11.99	0.78	4.36	399	214	111	147	39
Minimum	1.46	0.04	0.10	12	0	4	9	0
Maximum	16.04	2.22	8.81	1134	727	373	626	128

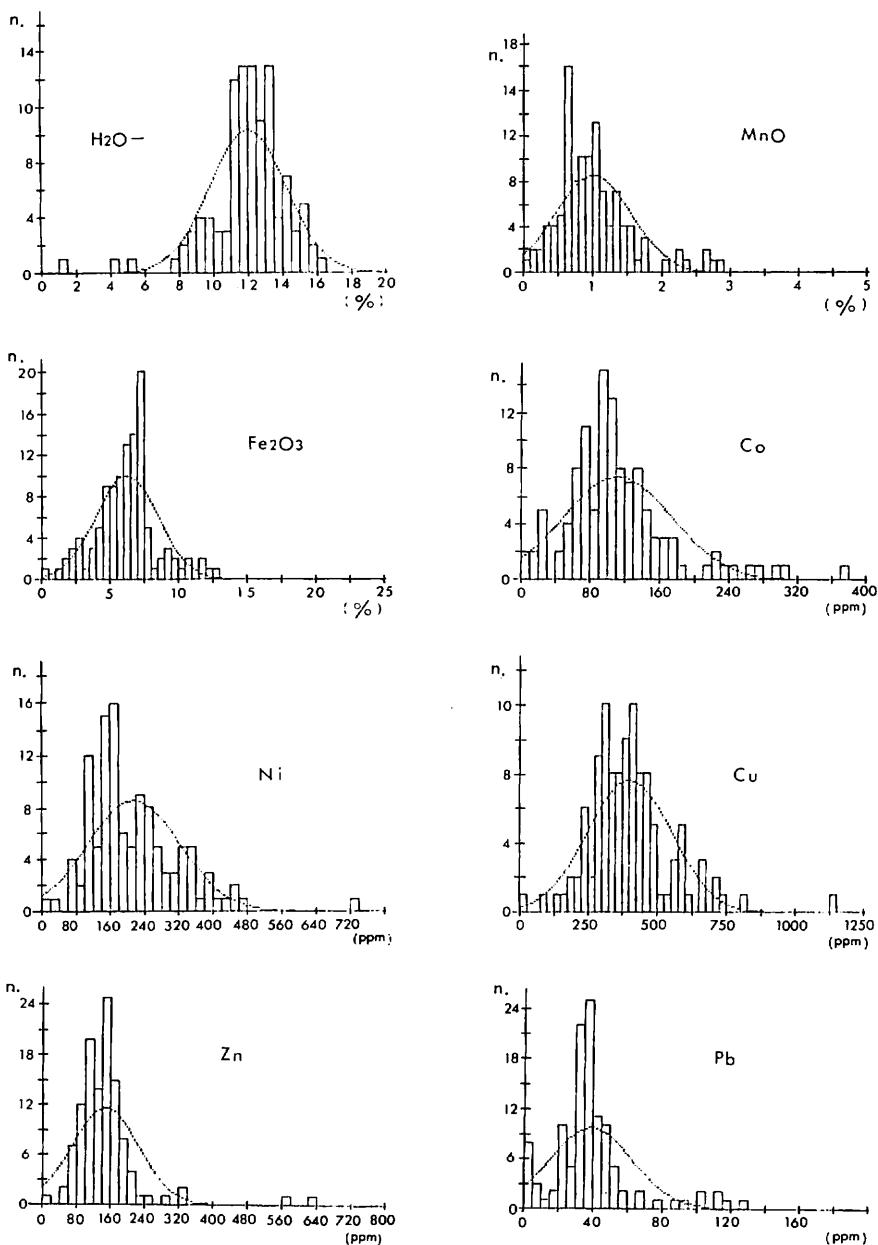

Fig. XV-1 The histograms of the minor element and the moisture contents in the bottom sediments.

almost identical type and the others are right or left skewed type as follows.

- 1) The distributions of Cu and Zn contents are almost identical types comparing their histograms with normal distribution curves.
- 2) The distributions of Mn, Co, Ni, and Pb contents are left skewed in comparison with normal distribution curves. Especially, the strong tendency of skewness as to the

distribution of Ni content is observed.

3) The distributions of Fe and moisture content are right skewed in comparison with normal distribution curves.

The skewness of their distributions mentioned above suggests that the presence of the minor elements are somewhat heterogeneous in the gross sediments from the GH80-1 survey traverses. Further discussion based on the classification of sediments (NAKAO and MIZUNO, this cruise report) are required in this respect. Associating with the subjects mentioned above, some of the information are pointed out as follows by taking a general view for the horizontal distribution of the minor elements mainly according to the surface sediments.

Manganese is the most typical element changing its content in concordance with the change of sedimentary facies at and near the sea bottom surface. Higher values ($\geq 0.5\%$ Mn, on the 110°C dry basis) appear in pelagic clay or zeolitic sediments. While lower ones ($\leq 0.1\%$) do in calcareous ooze and intermediate (0.1–0.5%) ones in siliceous sediments in general. And it should be noted that unusual high values, including more than 2% (2.22% at St. 1618A, B16), appears in zeolitic clay or pelagic clay in the Penrhyn Basin. Other elements have more or less similar tendency with Mn except for the cases of Cu and Pb. For Cu, there is no difference between the values in the northern pelagic clay and zeolitic sediments and in the siliceous sediments. And for Pb, rather higher values (not the highest, 40–60 ppm) appears not in the north pelagic clay or zeolitic sediments but in calcareous or siliceous-calcareous sediments.

Relations among the elements

The coefficients of correlation among each components are shown in Table XV-2. The strength patterns of the correlation are shown in Fig. XV-2. Some of the information

Table XV-2 The correlation coefficient table of the minor elements and the moisture in the bottom sediments. The coefficients were recalculated for 115 samples on the basis of the dried state (110°C).

	H ₂ O	Mn	Fe	Co	Ni	Cu	Zn	Pb
Mn	0.10							
Fe	0.20	0.80						
Co	0.08	0.78	0.77					
Ni	0.18	0.70	0.49	0.75				
Cu	0.34	0.52	0.43	0.45	0.69			
Zn	0.20	0.35	0.33	0.30	0.39	0.40		
Pb	0.01	0.79	0.83	0.83	0.47	0.25	0.17	

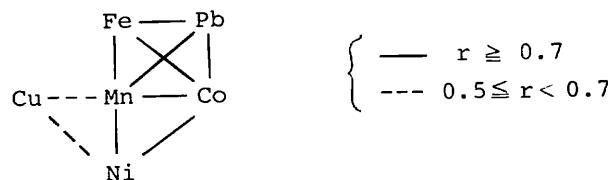

Fig. XV-2 The strength patterns of the correlations among the minor elements in the bottom sediments.

are obtained as follows.

- 1) A correlation between moisture content and the others is scarcely observed.
- 2) A correlation between Zn content and the others is not appreciably observed.
- 3) A strong correlation is observed between Mn and Fe, Co, Ni, or Pb (correlation coefficient, $r \geq 0.7$).
- 4) Among Mn, Fe, Co, and Pb, a strong correlation is observed to each other ($r \geq 0.7$).
- 5) A strong correlation is observed between Ni and Mn or Co ($r \geq 0.7$).
- 6) A medium correlation is observed between Cu and Mn or Ni ($0.5 \leq r < 0.7$).

The metallic elements such as Mn, Fe, Co, Ni, Cu, Zn, and Pb will be present at various states in the sediments. The particles which constitute the deep-sea sediments are classified as terrigenous, volcanicogenic, biogenic, and chemogenic ones and furthermore diagenetic one originated from these. According to NAKAO and KATO, and NAKAO *et al.* (both in preparation), it has been considered that at least the majority of manganese (about 90%) exist as the diagenetic and the chemical origin particles (manganese micronodules) which can be easily dissolved or extracted by the mixed solution of acetic acid and hydroxylamine hydrochloride. While their works show only ca. 20% of total Fe and ca. 50% of total Cu do in the extractive states in deep-sea sediments. In other words, 80% of total Fe should be in the crystal structure of minerals which cannot be destroyed by that solution. Therefore, it seems that different factors control the concentration of Mn and especially Fe. Present results, however, show rather intimate relations among those elements including Fe, suggesting the presence of some common factors controlling their distribution in sediments. Further study is required to solve this problem, though maybe the presence of iron-monmolliolomite (AOKI, this cruise report) is one of the relating aspects.
